

system of classes that work in similar ways, making a system predictable to client programmers.

I also discussed the idea of polymorphism in operators, explaining how the same operator could do different operations with different types of data. I showed how Python's magic methods are used to make this happen and how you can build methods to implement these operators in your own classes. To demonstrate the use of arithmetic and comparison operator magic methods, I showed a `Vector` class and a `Fraction` class. I also showed how you can use the `__str__()` method to help in debugging the content of an object.
